Abstract. Using N -body simulations we study the evolution of separate stellar populations in dwarf galaxies in the context of the tidal stirring scenario for the formation of dwarf spheroidal (dSph) galaxies in the Local Group. The dwarf galaxies, initially composed of a stellar disk and a dark matter halo, are placed on seven different orbits around the Milky Way. The stars are divided into two populations, within and outside the half-light radius, and their positions are followed for 10 Gyr. We find that the populations retain different density distributions even over such long timescales. Some of the stars of the outer population migrate to the central part of the dwarf forming an extended core while the stars of the inner population develop a tail in the outer parts. In addition, the outer population is more heavily stripped by tidal forces from the Milky Way and may become subdominant at all radii on tight enough orbits. We conclude that the tidal stirring model is fully compatible with the presence of multiple stellar populations in dSph galaxies.

Key words. galaxies: dwarf — galaxies: fundamental parameters — galaxies: kinematics and dynamics — galaxies: structure — Local Group

1. Introduction

Dwarf spheroidal (dSph) galaxies of the Local Group provide unique laboratory for studying the processes of galaxy formation and evolution. Their relative proximity has recently enabled detailed probing of density distributions and kinematics, as well as metallicities of their stellar components. These observational studies have revealed the presence of multiple stellar populations in the dwarfs, differing by metallicity and age. The populations thus identified

were shown to be distributed differently in space and possess various velocity distributions as quantified e.g. by their velocity dispersion profiles (Tolstoy et al. 2004; Koch et al. 2006; Battaglia et al. 2008; Kirby et al. 2011; de Boer et al. 2012). The presence of multiple stellar populations has been invoked as a possible explanation for anomalous velocity dispersion profiles observed in some dSph galaxies (Ibata et al. 2006; McConnachie et al. 2007). It has also recently proved useful in constraining the density slope of dSph galaxies (Walker & Peñarrubia 2011).

Table 1. Parameters of the simulated dwarfs

Orbit	r_{apo} [kpc]	r_{peri} [kpc]	$r_{\text{apo}}/r_{\text{peri}}$	T_{orb} [Gyr]	n_{peri}	M_V [mag]	$r_{1/2}$ [kpc]	μ_V [mag arcsec ⁻²]
O1	125	25	5	2.09	5	-11.5	0.32	23.4
O2	85	17	5	1.28	8	-10.0	0.35	24.8
O3	250	50	5	5.40	2	-12.4	0.62	23.8
O4	125	12.5	10	1.81	6	-9.7	0.25	24.7
O5	125	50	2.5	2.50	4	-12.3	0.41	22.9
O6	80	50	1.6	1.70	6	-12.2	0.43	23.3
O7	250	12.5	20	4.55	2	-11.7	0.39	23.5

Substantial progress has also been achieved in theoretical modelling of the formation of dSph galaxies. One promising scenario for their origin invokes tidal evolution in the vicinity of more massive galaxies like the Milky Way or Andromeda (Mayer et al. 2001). The tidal stirring model envisions the present-day dSph galaxies as products of the repeated action of the tidal force from the host galaxy on a late-type progenitor accreted a few Gyr ago, thus explaining naturally the observed morphology-density relation in the Local Group. The process can be reliably modelled using N -body simulations which demonstrate that such evolution is indeed feasible over reasonable timescales (Klimentowski et al. 2009; Kazantzidis et al. 2011). The transformation from disks to spheroids is accompanied by randomization of stellar orbits and strong mass loss due to tidal stripping.

The morphological evolution typically involves a bar-like stage (Łokas et al. 2012) and therefore a question arises what effect the instability associated with bar formation may have on the properties of stellar populations present in the dwarf galaxy. Since most of the stars in dSph galaxies are old, they have probably formed before the dwarf’s progenitor was accreted by the host. Although some star formation may occur as a result of tidal stirring, the amount of new stars is probably not large as the gas reservoir is likely to be depleted quickly by ram pressure stripping (Mayer et al. 2007). In this work we address the ques-

tion whether the separate stellar populations present in the progenitor prior to accretion are likely to survive until the present time. Such considerations may put some constraints on the amount of tidal stirring experienced by dSph galaxies in our vicinity.

2. The simulations

For the present study we used a subset of tidal stirring simulations described in detail in Kazantzidis et al. (2011) and Łokas et al. (2011). Our dwarf galaxy was initially composed of an exponential stellar disk of mass $2 \times 10^7 M_\odot$ embedded in a dark matter halo of virial mass $10^9 M_\odot$ and an NFW (Navarro et al. 1996) density profile with concentration $c = 20$. The N -body realization of the dwarf contained 1.2×10^6 stars and 10^6 dark matter particles. The dwarf galaxy was placed on seven different orbits (initially at the apocenter) around a host galaxy with the present-day properties of the Milky Way (Widrow & Dubinski 2005) and its evolution was followed for 10 Gyr with the PKDGRAV code (Stadel 2001).

The orbital parameters of the simulations are listed in Table 1. Columns 2-6 of the Table give respectively the apocenter r_{apo} , the pericenter r_{peri} , the ratio of the two distances, the orbital time and the number of pericenters passed during the 10 Gyr of evolution. The orbits cover a large range of sizes and eccentricities resulting in different amounts of tidal

Fig. 1. Evolution of the density profiles of stars in the inner Population 1 (dashed lines) and the outer Population 2 (solid lines) for the dwarf galaxy on orbit O1. The populations are initially divided by the half-light radius (upper left panel). The panels (from the upper left to the lower right) show the density profiles at subsequent apocenters of the orbit and at the final stage. The times of the measurements are given in each panel.

force experienced by the dwarf galaxy. The last three columns of Table 1 list the observational parameters of the dwarfs at the final stage as they would be measured by an imaginary observer at the center of the Milky Way: the absolute magnitude, the projected half-light radius and the central surface brightness (Łokas et al. 2011). The parameters fall in the ranges occupied by the classical dSph galaxies in the vicinity of the Milky Way.

3. Evolution of stellar populations

In order to see how stellar populations may be affected by tidal evolution we divided the stellar component of the dwarf galaxy into two populations, each containing initially half of the total number of stars. The inner population (Population 1) was selected to contain all stars with radii $r < r_{1/2}$ and the outer population

(Population 2) all stars with $r > r_{1/2}$ where $r_{1/2} = 0.7$ kpc is the three-dimensional half-light radius of the initial stellar disk. Although quite simplistic, the division probably reflects to some extent the actual distribution of stars of different metallicity following from multiple star formation episodes. The stars formed later are likely to be produced from the gas expelled at earlier stages which was later accreted and sunk to the center of the dwarf galaxy resulting in the segregation of populations with different stellar properties.

The positions of the stars in each population were traced for the whole evolution time. Figure 1 shows the density profiles of the stars in the two populations at the initial time, the subsequent apocenters and at the final output for orbit O1, which may be considered a typical orbit of dwarf galaxies in the vicinity of the Milky Way (Diemand et al. 2007;

Fig. 2. The density profiles of stars in the inner Population 1 (dashed lines) and the outer Population 2 (solid lines) at the end of evolution (after 10 Gyr) for orbits O2-O7 (from the upper left to the lower right panel). The populations were initially divided by the half-light radius (as in the upper left panel of Figure 1).

Klimontowski et al. 2010). Although the stars of the two populations were initially spatially separated, as the evolution proceeds the outer population tends to populate the inner region forming a core-like distribution, while the inner population extends to larger radii forming a tail. The stars are lost from both populations due to tidal forces, as confirmed by the decreasing normalization of the density profiles. For most of the time, Population 1 dominates in the center, and Population 2 in the outer parts. However, with time the outer population is more heavily stripped and gradually becomes subdominant at all radii. In addition, both components display a flattening of their respective density profiles at radii $r > 1$ kpc signifying the transition to tidal tails.

As expected, the final outcome of the evolution depends sensitively on the orbit on which the dwarf is accreted. We illustrate this in Figure 2 which shows the final density pro-

files of the two populations on orbits O2-O7. The populations were defined initially in exactly the same way as for orbit O1. We see that on the very tight orbit O2 and the one with the smallest pericenter O4 the outer population is very strongly stripped and very few stars of this population are still bound to the dwarf. On the other hand, the less tight orbits O3, O5 and O6 allow both populations to survive and retain their different distributions. The most eccentric orbit O7 is an interesting intermediate case.

4. Conclusions

Using N -body simulations of dwarf galaxies orbiting the Milky Way we have studied the evolution of separate stellar populations in dwarfs. We have shown that in spite of repeated action of tidal forces at pericenters, the differences in the distribution of stellar populations survive over timescales comparable to the present age of the Universe. The stars

of the inner stellar component migrate outwards and the ones of the outer one inwards populating the regions initially devoid of the stars of each type. Still, the populations do not mix completely and the density profiles of the two components remain distinguishable. The inner component remains more centrally concentrated and the outer one more extended so that their respective characteristic radii (e.g. the half-light radii) at present may be very different. In general, the more extended population is stripped more effectively and thus may become subdominant at all radii for sufficiently tight orbits.

We have demonstrated that the presence of multiple stellar populations in dSph galaxies of the Local Group is entirely consistent with the tidal stirring scenario which envisions their formation as following from interactions of late-type progenitors with a Milky Way-like host galaxies. Even with the instability inherent to the bar formation usually taking place at the first pericenter passage, the separate populations do survive. This should be the case also for the generic example of such interactions, namely the Sagittarius dwarf, which moves around the Milky Way on a rather tight orbit and is thus subject to particularly strong tidal effects resulting in the formation of pronounced tidal tails (Majewski et al. 2003; Law et al. 2005; Łokas et al. 2010). Indeed, the presence of multiple stellar populations in Sagittarius and its tidal tails is well established observationally (Siegel et al. 2007; Chou et al. 2007).
